Formation control for autonomous robots with collision and obstacle avoidance using a rotational and repulsive force–based approach

Anh Duc Dang\textsuperscript{1}, Hung Manh La\textsuperscript{2}, Thang Nguyen\textsuperscript{3} and Joachim Horn\textsuperscript{1}

Abstract
In this article, we address a formation control problem for a group of autonomous robots to track a moving target in the presence of obstacles. In the proposed method, desired formations, which consist of virtual nodes arranged in specific shapes, are first generated. Then, autonomous robots are driven toward these virtual nodes without collisions with each other using a novel control scheme, which is based on artificial force fields. The convergence analysis is shown based on Lyapunov’s stability. The novelty of the proposed approach lies in a new combination of rotational force field and repulsive force field to design a mechanism so that robots can avoid and escape complex obstacle shapes. The effectiveness of the proposed method is illustrated with numerical examples using V-shape and circular shape formations.

Introduction
Research activities in multiagent systems have offered a wide range of applications in various areas such as physics, biology, cybernetics, and agriculture. In the field of multiagent systems, one of the most important problems is formation control, in which agents in the system are required to form desired shapes. Typical potential applications in formation control include search and rescue missions, forest fire detection and surveillance, source seeking, and so on. Autonomous robots of a multiagent system can be underwater vehicles\textsuperscript{1,2} unmanned aerial vehicles,\textsuperscript{3,4} mobile sensor networks,\textsuperscript{5–12} rectangular agents,\textsuperscript{13} and non-holonomic mobile robots.\textsuperscript{14–18}

Centralized control protocols have been constructed based on the common assumption that the information of all agents is available or the multiagent system possesses all-to-all communication. The drawbacks of the centralized...
communication control architecture are inflexibility and large computational costs for each controller for each agent especially when the number of robots is large. In contrast, a distributed or decentralized control approach can provide more flexibility, easier implementation, and less computational loads as the controller of each agent only requires the information of its neighbor agents.\textsuperscript{6,7,18–21}

In formation control of a multiagent system, desired tasks of the system, such as tracking a moving target, are executed by the cooperation of a robot team. The formation control problem of autonomous robots is motivated by natural behaviors of creatures such as fish schooling, bird flocking, or ant swarming. Here, the members in the formation are required to collaborate with others to achieve common goals such as velocity matching and collision avoidance. The formation of a swarm of mobile robots can be generated and controlled by different methods in the literature. It is well-known that the artificial potential field method plays a pivotal role in controlling the coordination and the motion of a swarm so that its agents move toward target positions.\textsuperscript{22–28} It is well established that the potential field method generates attractive forces for mobile robots to avoid collision and maintain distances in coordination control problems.\textsuperscript{5} Many works on the formation control method using the random connections among neighboring members in a swarm as an \(\alpha\)-lattice configuration were reported in a variety of papers.\textsuperscript{5–12,29,30}

In this direction, the attractive/repulsive force fields are employed to link neighboring robots so that a robust formation without collisions is established. In a different approach, a dynamic framework was introduced by Hou et al.\textsuperscript{31} and Cheah et al.,\textsuperscript{32} in which the robots of a swarm can adapt their formation by rotating and scaling during their movement. Similarly, the attractive/repulsive force fields were also utilized by Eren\textsuperscript{33} to control robots to converge to given positions of a desired shape.

Although the artificial potential field has been regarded as a powerful tool for path planning of mobile robots, it still possesses some limitations due to local minimum problems. This can lead to a situation where a robot can get stuck if facing with an obstacle. In this context, the attractive force of the target and the repulsive force of the obstacles are equal and collinear but in an opposite direction. As a result, the total force on the robot is equal to zero, which traps the robot there. In addition, the traditional potential field method exhibits shortcomings in complex environments which contain convex and concave obstacle shapes, such as U-shaped obstacles or long walls and so on. When facing with these kinds of obstacles, robots can be trapped in them, and hence prevented from reaching targets.\textsuperscript{34} The summary of related work is shown in Table 1. Recent research methods were proposed to address local minima avoidance\textsuperscript{41,42} that the reader can refer to.

In many studies, the dynamics of agents are modeled as single integrator,\textsuperscript{13,43,44} double integrators,\textsuperscript{5,7,10,45,46} and unicycles.\textsuperscript{47,48} In narrow space, the shapes of agents are taken into consideration for the formation control problem.\textsuperscript{13,44} In this article, a formation control problem for point-based agents with double-integrator dynamics is addressed. Theoretical development of the paper sets a framework, which can be employed to design a formation control system for various agents with more complicated dynamics and shapes. The particle model in this article has been extensively used in previous work. The work of Olfati-Saber\textsuperscript{7} presents a

Theoretical framework for design and analysis of distributed flocking algorithms using the double-integrator dynamics for the dynamics of an agent. In applications, it is employed to model mobile robots that have omnidirectional motion capability, such as the Rovio mobile robots. It is also used in theoretical work for mobile sensor networks.

The main contributions of this article are in the following. The formation control algorithms are designed to drive multiple robots to converge to the desired positions to capture a moving target while avoiding collision with other agents and obstacles. However, the communication is still all-to-all since there is a need to compare the distances of agents to the target to choose the leader of the swarm. Once the leader is chosen, the control law of an agent is calculated based on the positions and velocities of its neighboring agents. In this case, the control algorithm is distributed, which helps save computational costs. The stability of the formation is maintained and collision avoidance among robots is obtained while the swarm tracks a moving target. In addition, the novelty of the article lies in the combination of the rotational and repulsive force fields, from which the obstacle avoidance control algorithm is constructed to drive robots to escape obstacles without collisions.

The structure of the article is organized as follows. In section Formulation, the problem formulation is presented. In section Control algorithms, the formation control algorithms are presented. Section Case study presents a case study for two typical examples of V-shape and circular shape formation control. Section Simulation results presents some simulation results. Finally, section Conclusion concludes the article with some remarks and future research topics.

Problem formulation

In this article, a swarm of $N$ robots is considered with their mission of tracking a moving target in two-dimensional space. Let $p_i = (x_i, y_i)^T$ and $v_i = (v_{ix}, v_{iy})^T$ be the position and velocity vectors of robot $i$ ($i = 1, 2, 3, ..., N$), respectively. The dynamic model of robot $i$ is

$$\begin{align*}
\dot{p}_i &= v_i \\
\dot{v}_i &= u_i
\end{align*}$$

for $i = 1, 2, 3, ..., N$.

Conditions for a formation of autonomous robots are as follows:

a. There are no collisions among robots.

b. Robots must converge to the desired positions.

c. Robots must avoid collision with obstacles.

d. The formation must be maintained under the influence of the environment.

A desired formation of a multi-robot system consists of virtual nodes which will be occupied by the robots of the system. To facilitate the control design and analysis, we introduce the following definitions.

Definition 1.
In the desired formation, a virtual node $j$ ($j = 1, 2, ..., N$) is a desired position for robot $i$, for which $\lim_{t \to \infty} \| p_i(t) - q_j(t) \| = 0$.

Definition 2.
Let $d_{p,q_j} < r_a$ be the distance of robot $i$ to virtual node $j$ ($j = 1, 2, 3, ..., N$). If $d_{p,q_j} < r_a$, where $r_a = d/2 - \lambda_a$, $d$ is the distance between two neighbor virtual nodes, and $\lambda_a$ is a positive constant, then robot $i$ is an active robot. Otherwise, it is called a free robot. Here, $r_a$ is denoted as the radius of the active circle surrounding the virtual node (see Figure 1).

Definition 3.
Let $l$ denote the index of the current leader of the swarm.

Definition 4.
In the desired formation, virtual node $j$ is called an active node if a robot $i$ ($i = 1, 2, 3, ..., N$) lies in the active circle of the virtual node $j$ (see Figure 1). Otherwise, it is called a free virtual node.

Definition 5.
The desired V-shape formation consists of two line formations. These line formations are driven by a selected leader and connected by a formation angle $\phi$. In each line of the formation, the virtual nodes are equidistant to its neighboring ones.

Definition 6.
The desired circular shape formation is a circle in which all virtual nodes are distributed evenly on the circle and the target lies in the center of the circle.

Definition 7.
Let $\mathcal{N}_i^l(t)$ be the set of the neighboring robots of the robot $i$ at time $t$, such that
\[ N^k_i(t) = \{ \forall k : d^k_i = \| p_j - p_k \| \leq r_k, k \in 1, \ldots, N, k \neq i \} \]  

where \( r_k \) is the repulsive radius surrounding each robot, and \( d^k_i \) is the Euclidean distance between robots \( k \) and \( i \).

**Definition 8.** A set of the neighboring obstacles of robot \( i \) at time \( t \) is defined as

\[
O^o_i(t) = \{ \forall k : d_{ioi} \leq r_{b}, k \in 1, \ldots, M \}
\]

where \( r_{b} > 0 \), \( M \) is the number of obstacles, and \( d_{ioi} = \| p_j - p_o \| \) are the obstacle detection range and the Euclidean distance between robot \( i \) and obstacle \( o_k \), respectively.

**Control algorithms**

This section presents control algorithms to guarantee that all robots will converge to their desired positions in the desired formation. While tracking a moving target, collision and obstacle avoidance of the swarm must be achieved.

**Control architecture**

To address our problem, we propose the control input \( u_i \) for each robot as follows

\[
u_i = \begin{cases} 
u'_i + u''_i & \text{if robot } i \text{ is a leader} \\ u'_i + u''_i + u''_i & \text{otherwise} \end{cases}
\]

where \( u'_i \) is used to control the formation connection, \( u''_i \) drives robots to avoid obstacles, \( u''_i \) helps robots avoid collision during the motion of the swarm, and \( u''_i \) serves as a tracking controller. Hence, it can drive the leader of the swarm to move toward the target. In equation (4), when collision avoidance for robot \( i \) is active, other robots lie in its repulsive radius \( r_r \), which activates \( u''_i \). Similarly, when an obstacle lies in the obstacle sensing range \( r_b \), collision avoidance is active, leading to the activation of \( u''_i \). The stability analysis of the main results in this article will be based on Lyapunov’s stability theorem.

**Formation connection control algorithm**

Initially, there exists an attractive force field for each virtual node \( j (j = 1, 2, \ldots, N) \). The resulting attractive force fields drive free robots to move toward their desired positions. The free robots will then become active and will occupy these desired positions. The tracking control objective for each robot is to make the distance between robot \( i \) and virtual node \( j (d_{ij} = \| p_j - p_i \|) \) approach zero as fast as possible. In other words, \( \lim_{t \to \infty} \| p_j - p_i \| = 0 \) and \( \lim_{t \to \infty} \| v_j - v_i \| = 0 \). Based on the above argument, the formation control law for formation connection is presented in algorithm 1.

**Algorithm 1.** Reaching the desired positions at the virtual nodes in the desired formation.

Consider a robot \( i \) and virtual nodes \( j (i, j = 1, \ldots, N, i \neq j) \). Determine the shortest distance from \( p_j \) to all the virtual nodes \( q_j \) and the scalar constant \( c^j_i \):

\[
d_{ij} = \min \{d_{p_jq_j} = \| p_i - q_j \| : j = 1, \ldots, N \}
\]

\[
c^j_i = \begin{cases} 1, & \text{if } q_j \text{ is active} \\ 0, & \text{if } q_j \text{ is free} \end{cases}
\]

where \( j_1 \) is the virtual node whose distance to robot \( i \) is shortest.

**In algorithm 1, \( k^1_i \), \( k^2_i \), \( k^3_i \), and \( k^4_i \) are positive constants; \( \| p_j - q_j \| \) and \( \| v_j - v_i \| \) are the relative position and velocity vectors between robot \( i \) and virtual node \( j \), respectively. Two potential fields \( f^1_i = -k^1_i \| p_i - q_j \| \| p_i - q_j \| \) and \( f^2_i = -k^2_i \| p_i - q_j \| \) are employed as the artificial attractive forces. Free robots are driven toward the desired...**
formation using the constant potential field $f_{ij}^1$, while active robots are controlled to approach the virtual nodes using the linear potential field $f_{ij}^2$. In addition, the component $-\kappa_i^1(v_i - v_j)$ serves as a damping term. Thus, using algorithm 1, the robots of the swarm can quickly converge to the desired positions, which are the virtual nodes of the desired formation. The stability of the formation is stated in the following.

**Theorem 1.** Consider the active robot $i$ with its dynamic model (1) and control input $u_i^l$ given in algorithm 1 at the active node $j$ in the desired formation. If the velocity of node $j$ is smaller than the maximum velocity of robot $i$, and node $j - 1$ is also active, then the system (1) will converge to the equilibrium state, at which $p_i = q_j$ and $v_i = v_j$ for all $i$ and $j$.

**Proof.** In order to analyze the stability of the robot $i$ at the active node $j$ when the node $j - 1$ is also active, we rewrite the control law $u_i^l$ as follows

$$u_i^l = f_{ij}^2 - \kappa_i^1(v_i - v_j) + v_j$$  \hspace{1cm} (5)

Consider the vector field $f_{ij}^2 = -\kappa_i^1(p_i - p_j) = (P_i, Q_i, Z_i)^T$ where $P_i = \kappa_i^p_1(x_i - x_j)$, $Q_i = \kappa_i^p_1(y_i - y_j)$, and $Z_i = 0$. According to Freeman and Kokotovic, we obtain

$$\text{rot}(f_{ij}^2) = \left( \frac{\partial Z_i}{\partial y_j} - \frac{\partial Q_i}{\partial x_i} - \frac{\partial P_i}{\partial x_j} + \frac{\partial Q_i}{\partial y_j} - \frac{\partial P_i}{\partial y_j} \right) = 0$$

Equation (6) shows that the vector field $f_{ij}^2$ is irrotational. Consider the scale function

$$V_{ij} = \frac{1}{2} \kappa_i^p_1(p_i - q_j)(p_i - q_j)^T$$  \hspace{1cm} (7)

Taking the negative gradient of the function $V_{ij}$, we obtain

$$-\nabla V_{ij} = -\nabla \left( \frac{1}{2} \kappa_i^p_1(p_i - q_j)(p_i - q_j)^T \right)$$

$$= -\nabla \left( \frac{1}{2} \kappa_i^p_1 ((x_i - x_j)^2 + (y_i - y_j)^2) \right)$$

$$= \left( -\frac{1}{2} \kappa_i^p_1 \frac{\partial}{\partial x_j} ((x_i - x_j)^2 + (y_i - y_j)^2) \right)^T$$

$$= \left( -\frac{1}{2} \kappa_i^p_1 \frac{\partial}{\partial y_j} ((x_i - x_j)^2 + (y_i - y_j)^2) \right)^T$$

$$= \left( -\kappa_i^p_1 (x_i - x_j) + \kappa_i^p_1 (y_i - y_j) \right)^T$$

$$= -\kappa_i^p_1 (p_i - p_j)$$

$$= f_{ij}^2$$

Equations (6) and (8) show that the vector field $f_{ij}^2$ is a potential field, and its potential function is $V_{ij}^1$.

Let $\bar{x}_i = p_i - q_i$ and $\bar{y}_j = v_i - v_j$ be the relative position and velocity of the robot $i$ and node $j$, respectively. The error dynamic model of the system is given as

$$\dot{x}_i = \bar{x}_i$$

$$\dot{\bar{y}}_j = u_j^l - \bar{v}_j$$  \hspace{1cm} (9)

From equations (5) and (9),

$$\ddot{x} = A\ddot{x}$$

where $\ddot{x} = (\bar{x}_1, \bar{x}_2)^T$ and

$$A = \begin{bmatrix} O_2 & I_2 \\ -\kappa_i^p_1 I_2 & -\kappa_i^p_2 I_2 \end{bmatrix}$$

where $O_2$ is the zero matrix of 2 and $I_2$ is the identity matrix of 2. It can easily be shown that the eigenvalues of matrix $A$ are the roots of the polynomial $s^2 + \kappa_i^p_1 s + \kappa_i^p_2$, which have negative real parts since $\kappa_i^p_1$ is positive. Hence, the system (11) is asymptotically stable.

**Remark 1.** It is well established that the Lyapunov theory is employed for the stability proof of formation and flock control of multiagent systems. For more information about the Lyapunov theory, the reader is referred to the work of Freeman and Kokotovic and Khalil.

**Remark 2.** Figure 1 illustrates a desired formation (V-shape or circular shape formation) of $N$ virtual nodes. The desired formation contains a desired position for each robot. Algorithm 1 allows each free robot $i$ to firstly seek its closest free virtual node (for instance, $j$) so that it will be active at this virtual node. If the position of an active robot $i$ is still not at the desired one (e.g. robot $k$ in Figure 1 with $k = 1, 2, ..., N, k \neq i$), then it will automatically move to virtual node ($j - 1$) until it occupies the desired position.

In order to allow robot $i$ to approach node $j$ as fast as possible, we use the attractive force from node $j$, which is proportional to its velocity. This means that the factor $\kappa_i^p$ in algorithm 1 depends on the velocity $v_j$. This factor is given as

$$\kappa_i^p = \kappa_i^{pd} + \varepsilon_1 \| v_j \|$$  \hspace{1cm} (13)

where $\kappa_i^{pd}$ and $\varepsilon_1$ are positive.

**Collision avoidance control algorithm**

This section presents a method for the collision avoidance among the robots during their movement based on the artificial repulsive potential field. The potential field has been widely used in addressing flocking and formation control of multiagent systems. In general, a potential function $\zeta(\cdot)$, which depends on the distance among agents or between agents and obstacles, is constructed. A typical feedback
control law consists of two parts: the gradient of the potential function and the velocity consensus term.\(^5,9,22\)–\(^24\)

In order to avoid the collision between robots \(i\) and \(k\) (\(i, k = 1, 2, ..., N; i \neq k \neq l\)), the local repulsive force field is created surrounding each robot within the repulsive radius \(r_i\) as

\[
f_{ik} = \left( \frac{1}{d_{ik}} - \frac{1}{r_i} \right) \kappa_i^{c1} \left( \frac{d_{ik}}{r_i} \right)^2 - \kappa_i^{c2} \left( d_{ik} - r_i \right) c_{ik}n_{ik} \quad (14)
\]

where positive constants \(\kappa_i^{c1}\) and \(\kappa_i^{c2}\) are employed to deal with fast interaction. The unit vector from robots \(k\) to \(i\) is described as \(n_{ik} = (p_i - p_k) / \| p_i - p_k \|\). The scalar \(c_{ik}\) is defined as

\[
c_{ik} = \begin{cases} 1, & \text{if } k \in \mathcal{N}_i(t) \\ 0, & \text{otherwise} \end{cases} \quad (15)
\]

The algorithm for the collision avoidance is built based on the repulsive force field \(14\) combined with the relative velocity vector \(\kappa_i^{c}(v_i - v_k)\) between robots \(k\) and \(i\) as follows

\[
u_i = \sum_{k=1, k \neq i}^N (f_{ik} - c_{ik} \kappa_i^{c}(v_i - v_k)) \quad (16)
\]

The controller \(16\) reveals that neighboring robots are controlled to leave each other when distances among them are too close. As in the study of Olfati-Saber,\(^5\) we employ repulsive fields to avoid collision among agents. The analysis is quite similar to that in the study of Olfati-Saber.\(^5\) Therefore, our control mechanism guarantees that collision avoidance in the swarm is achieved.

**Obstacle avoidance control algorithm**

This section presents a control algorithm for robots to pass through \(M\) obstacles. The obstacle avoidance control algorithm for each member robot \(i\) \((i = 1, 2, ..., N)\) is designed as follows

\[
u_i^o = \sum_{h=1}^M \left( f_{ih}^{op} + f_{ih}^{or} + \kappa_i^{o} c_{ih}^o(v_i - v_{oh}) \right) \quad (17)
\]

where relative velocity \((v_i - v_{oh})\) between robot \(i\) and its neighboring obstacle \(oh\) is utilized as a damping term with damping scaling factor \(\kappa_i^{o}\), and the scalar \(c_{ih}^o\) is defined as

\[
c_{ih}^o = \begin{cases} 1, & \text{if } h \in \mathcal{O}_i(t) \\ 0, & \text{otherwise} \end{cases} \quad (18)
\]

The repulsive force field \(f_{ih}^{op}\) is created to drive robot \(i\) to move away from its neighboring obstacle (see Figure 2). This force field is designed as

\[
f_{ih}^{op} = \left( \frac{1}{d_{ih}} - \frac{1}{r_i} \right) \kappa_i^{o1} \left( \frac{d_{ih}}{r_i} \right)^2 - \kappa_i^{o2} \left( d_{ih} - r_i \right) c_{ih}^o n_{ih} \quad (19)
\]

where positive factors \(\kappa_i^{o1}\) and \(\kappa_i^{o2}\) are used to control the fast obstacle avoidance, \(r_i\) is the obstacle detection range defined in definition 8, and \(n_{ih} = (p_i - p_{oh}) / \| p_i - p_{oh} \|\) is a unit vector.

In control law \(17\), the rotational force field (see Figure 3) is added to combine with the repulsive force (see Figure 2) to drive robot \(i\) to quickly escape its neighboring obstacle. While the potential force field is used to enable it to avoid collision with its neighboring obstacle, the rotational force field is used to solve the local minimum problems; for instance, the robot meets a trapping point, at which the repulsive force of the obstacles and the attractive force of the target are balanced. Under the effect of the added rotational force field, the robot always escapes this trapping point. Furthermore, when robot is trapped in complex obstacles (e.g. U-shape or long wall), the rotational vector field will help it find a new path to escape these obstacles. The direction of the rotational force can be clockwise or counter clockwise (see Figure 3). Hence, this rotational force is built as

\[
f_{ih}^{or} = w_{ih}^c c_{ih}^o r_i \quad (20)
\]
where the unit vector $n_i^{or}$ is given as

$$n_i^{or} = c_i^{or} \left( \frac{(y_j - y_{o_h})}{d_{o_h}}, -\frac{(x_i - x_{o_h})}{d_{o_h}} \right)$$  \hspace{1cm} (21)$$

where the scalar $c_i^{or}$ is used to define the direction for the rotational force: the rotational force is clockwise if $c_i^{or} = 1$ and counter clockwise if $c_i^{or} = -1$. Now, we consider the relationship between this unit vector and the vector $p_i - p_{o_h}$.

Let $\sigma$ be the angle between these vectors. Then, we have

$$\cos \sigma = \frac{c_i^{or}(x_i - x_{o_h})(y_j - y_{o_h}) - (y_i - y_{o_h})(x_i - x_{o_h})}{(d_{o_h})^2} = 0$$  \hspace{1cm} (22)$$

Equation (22) shows that the unit vector is always perpendicular to vector $(p_i - p_{o_h})$. The positive gain factor $w_{o_h}$ in equation (20) is used as a control element to drive robots to quickly escape obstacles. Therefore, this control element is designed such that the total force on robots always has the direction in the selected rotational direction. This control element is given as follows

$$w_{o_h} = (1 + c)(\|f_i^{top}\| + \lambda_o)$$  \hspace{1cm} (23)$$

where $\lambda_o$ is a positive factor and the force $f_i^{top}$ is described as

$$f_i^{top} = f_{ij} + f_i^{op}$$  \hspace{1cm} (24)$$

where $f_i^{op}$ is the repulsive force from the neighboring obstacles of robot $i$, and $f_{ij}$ is the attractive force from the virtual node $j$ in the desired formation (see algorithm 1). The constant $c$ in equation (23), which depends on angle $\alpha$ between the sum vector $f_i^{top}$ and the unit vector $n_i^{or}$ (see Figure 4), is described as follows

$$c = \begin{cases} c_1, & \text{if } \alpha < \pi/2 \\ c_2, & \text{otherwise} \end{cases}$$  \hspace{1cm} (25)$$

where two constants $c_1$ and $c_2$ can be chosen as $-1 < c_1$, $0 < c_2$, and $c_1 < c_2$. Equation (23) guarantees that robot $i$ always moves in the direction of the rotational force $f_i^{or}$. Hence, it can easily escape the obstacles in order to continue with its swarm to track the moving target.

The total vector for the control law for agent $i$ is $f^s = f_i^{or} + f_i^{top}$. From equations (20) and (23), $\|f_i^{or}\| = w_{o_h}$. It is clear that when $\alpha < \pi/2$, the angle between $f^s$ and $n_{o_h}$ is smaller than $\pi/2$. When $\alpha \geq \pi/2$, $\|f_i^{or}\| = w_{o_h} > \|f_i^{top}\|$. This implies that the angle between $f^s$ and $n_{o_h}$ is smaller than $\alpha/2$, which is smaller than $\pi/2$. As a result, the total vector drives the agent to the direction to escape the obstacle (see Figure 4).

The obstacle avoidance analysis of the proposed scheme follows a similar approach as in theorem 6 in the technical report by Olfati-Saber.\textsuperscript{51} Unlike the method of Olfati-Saber,\textsuperscript{51} in our method, when an agent meets an obstacle, a rotational force field is generated which changes total force field. Hence, the direction of the agent is turned around the obstacle.

We summarize the above analysis in the following theorem.

\textbf{Theorem 2.} Consider the active robot $i$ with its dynamic model (1). If robot $i$ detects an obstacle in its obstacle
of complex obstacles in the future. An avoidance approach can work with a more general class for a class of complex obstacles (which can be large and nonconvex). This enables agents to escape the obstacles effectively. The constraint posed on a nonconvex obstacle is that the radius of the osculating circle of the obstacle is larger than \( r_j \), which is the obstacle detection range. The rotational field is only activated if the obstacle is in the obstacle detection range of the agent. However, if there are many rotational forces due to many obstacles, the control algorithm of the agent will have the rotational force from the obstacle with the highest priority.

**Remark 3.** The protocol for collision avoidance for the agents of the system in subsection Control architecture employs a repulsive force in equation (14). Here, the shapes of agents are simplified to be points or circles. In contrast, the obstacle avoidance in this section is realized using repulsive and rotational forces in equations (19) and (20) for a class of complex obstacles (which can be large and nonconvex). This enables agents to escape the obstacles effectively. The constraint posed on a nonconvex obstacle is that the radius of the osculating circle of the obstacle is larger than \( r_j \), which is the obstacle detection range. The rotational field is only activated if the obstacle is in the obstacle detection range of the agent. However, if there are many rotational forces due to many obstacles, the control algorithm of the agent will have the rotational force from the obstacle with the highest priority.

**Remark 4.** The complex obstacle used in our analysis is in a U-shape, which is nonconvex (see Figure 4). A rigorous study would be conducted to see whether our obstacle avoidance approach can work with a more general class of complex obstacles in the future.

**Target tracking control algorithm**

Firstly, a robot, which is closest to the target, is selected as the leader in order to generate the desired formation. Then, this leader leads its formation to track a moving target. When the leader encounters a risk, such as it is broken or trapped in obstacles, it must transfer its leadership to another, and becomes a free member robot in the swarm. The leader is selected as in algorithm 2.

The target tracking controller, which is designed based on the relative position between the leader and the target, has to guarantee that the formation’s motion is always driven toward the target. As introduced above, the V-shape and circular shape formations are utilized to track and encircle a moving target. Hence, the tracking task is to make the distance between the leader and the target \( d_l' = \| p_l - p_t \| \), approaching the radius of the desired circular formation \( r^* \) as fast as possible. This means that \( \lim_{t \to \infty} \| p_l - p_t \| = 0 \) and \( \lim_{t \to \infty} v_l - v_t \| = 0 \). Based on the above analysis, the control law for the target tracking is proposed as follows

\[
 u_l' = f_l' - \kappa_l^3 (v_l - v_t) + \dot{v}_t \tag{26}
\]

where \( \kappa_l^3 \) and \( v_t \) are the positive constant and the acceleration of the target, respectively, and \( v_l - v_t \) is the relative velocity vector between the leader and the target.

The potential field from the target is used to drive the leader moving toward the target, and is given by

\[
 f_l' = \begin{cases} 
 \left( \frac{1}{d_l'^2} - \frac{1}{r^*} \right) \kappa_l^3 \left( d_l' - r_t \right) n_l' \quad \text{if } d_l' < r^* \\
 \kappa_l^3 n_l' \quad \text{otherwise} \end{cases} \tag{27}
\]

where \( \kappa_l^3 \) is positive constants, and \( r_t \) is the target approaching radius and the desired radius of the circular formation \( r^* \), respectively. Here, \( \kappa_l^3 = \kappa_l^{d1} + \varepsilon_2 \| v_t \| \) where \( \kappa_l^{d1} \) and \( \varepsilon_2 \) are positive constants. The unit vector along the line connection from the target to the leader is computed as \( n_l' = (p_l - p_t) / \| p_l - p_t \| \). In equation (27), the constant attractive force \( f_{l1}' = -\kappa_l^1 n_l' \) is used to track the target when \( d_l' > r^* \). On the other hand, the attractive/repulsive force field surrounding the equilibrium position, at which \( \| p_l - p_t \| = r^* \) and \( v_l - v_t = 0 \), is employed to encircle the target when \( d_l' \leq r^* \). Hence, using this combined vector field, the leader can easily approach the target at the equilibrium position.

**Theorem 3.** Consider the leader l described by model (1) and governed by control law (26) when \( d_l' \leq r^* \). If the velocity of the target is smaller than the maximum velocity of the leader, then the system (1) will converge to the equilibrium state, at which \( v_l = v_t \) and \( (p_l - p_t) / \| p_l - p_t \| \).

**Proof.** Firstly, we consider the vector field \( f_{l1}' = K_l n_l' \) in equation (27), where \( K_l = (\kappa_l^3 / d_l' - \kappa_l^2 / r^*) (d_l')^2 - \)
\[ \kappa_i^1 (d_i^r - r') / (r' - r^r) \]  

Let \( P_i = K_i(x_i - x_i) / \| p_i - p_i \|, \)  
\( Q_i = K_i(y_i - y_i) / \| p_i - p_i \|, \)  
and \( Q_i = 0. \) Then, we have

\[ \text{rot}(f^r_i) = \left( \frac{\partial Z_i}{\partial y_i} - \frac{\partial Q_i}{\partial Z_i}, \frac{\partial P_i}{\partial Z_i} - \frac{\partial Z_i}{\partial x_i}, \frac{\partial Q_i}{\partial x_i} - \frac{\partial P_i}{\partial y_i} \right)^T = 0 \]  

(28)

Equation (28) shows that the vector field \( f^r_i \) is not rotational.

Consider the scale function

\[ V_i^r = \frac{1}{2} \left( \kappa_i^2 (d_i^r - r^r) / r^r \right)^2 + \kappa_i^1 (d_i^r - r^r)^2 / (r^r - r^r) \]  

(29)

Taking the negative gradient of \( V_i^r \), we obtain

\[ -\nabla V_i^r = -\nabla \left( \frac{\kappa_i^2}{2} \left( \frac{1}{d_i^r} - \frac{1}{r^r} \right)^2 \frac{\kappa_i^1 (d_i^r - r^r)^2}{2(r^r - r^r)} \right) \]

\[ = - \left( \frac{\kappa_i^2}{d_i^r} - \frac{\kappa_i^2}{r^r} \right) \nabla \left( \frac{1}{d_i^r} - \frac{1}{r^r} \right) \]

\[ - \kappa_i^1 (d_i^r - r^r) \left( \frac{r^r - r^r}{(r^r - r^r)} \right) \nabla d_i^r \]

\[ = \left( \frac{\kappa_i^2}{d_i^r} - \frac{\kappa_i^2}{r^r} \right) \frac{1}{(d_i^r)^2} \nabla d_i^r - \frac{\kappa_i^1 (d_i^r - r^r)}{(r^r - r^r)} \nabla d_i^r \]

\[ = \left( \frac{\kappa_i^2}{d_i^r} - \frac{\kappa_i^2}{r^r} \right) \frac{1}{(d_i^r)^2} \nabla d_i^r - \frac{\kappa_i^1 (d_i^r - r^r)}{(r^r - r^r)} (p_i - p_i) \]

\[ = f^r_i \]

(30)

Hence, equations (28) and (30) show that the vector field \( f^r_i \) is also a potential field, and its potential function is \( V_i^r \).

In order to analyze the stability of the leader at the equilibrium position, at which \( \| p_i - p_i \| = r' \) and \( y_i - y_i = 0 \), let \( \dot{x}_1 = p_i - p_i \) and \( \dot{x}_2 = y_i - y_i \). Then, the error dynamic of the system is described as

\[ \dot{x}_1 = \dot{x}_2 \]

\[ \dot{x}_2 = \ddot{y}_i - \dot{y}_i = u_i' - \dot{y}_i \]

(31)

(32)

From equations (26) and (31), we have

\[ \dot{x}_1 = \dot{x}_2 \]

\[ \ddot{x}_2 = \nabla V_i^r - \kappa_i^1 \dot{x}_2 \]

(33)

(34)

To analyze the stability of the system (33), we choose the following Lyapunov function candidate

\[ V_i = V_i^r + \frac{1}{2} \dot{x}_2^T \dot{x}_2 \]

(35)

Taking the time derivative of equation (35) along the trajectory of the system (33), we obtain

\[ \dot{V_i} = \nabla V_i^r \dot{x}_1 + \dot{x}_2^T \dot{x}_2 = \kappa_i^1 \dot{x}_2^T \dot{x}_2 \leq 0 \]

(36)

According to LaSalle’s theorem, \( \dot{x}_2 \rightarrow 0 \). It can easily be shown that \( \dot{x}_2 \) is uniformly continuous. Hence, according to Barbalat’s lemma, \( \dot{x}_2 \rightarrow 0 \).

\[ \frac{\partial}{\partial y_i} \left( K_i(x_i - x_i) / \| p_i - p_i \| \right) = \frac{\partial}{\partial y_i} \left( K_i(y_i - y_i) / \| p_i - p_i \| \right) = 0 \]

Remark 5. The formation of the swarm changes with respect to the relative position between the leader and the target. Initially, a robot will be chosen as a leader to lead its formation toward the target if it is closest to the target. During the motion of the swarm, if the current leader faces any risk (for instance, it is broken from the formation or hindered by the environment), then a new leader is nominated. Algorithm 2 guarantees that this new leader will reorganize the formation and continue to lead the swarm to track the target.

Remark 6. Obstacles in the environment can be sensed by several methods. Onboard sensors of each agent can detect them. In addition, hybrid approaches can employ a group of aerial drones to capture the images of obstacles and agents and transfer data to the agents.

Remark 7. The paper addressed the swarm tracking problem to capture a moving target in a specific formation using artificial potentials and sliding mode control. The dynamics used in this work are fully actuated. The artificial potentials are used for the formation and tracking control goals. Sliding techniques are used to deal with uncertainty, which exhibits robustness of the proposed control method. The control framework by Yao et al. was then applied for agents with nonholonomic dynamics by Gazi et al. Our control strategy shares the same principle as in the studies of Yao et al. and Gazi et al. where artificial potentials are employed for formation and target tracking control. On the one hand, the work of Yao et al. and Gazi et al. considers robustness issues, which we do not address in this article. On the other hand, our article deals with collision and obstacle avoidance, which are not included in the article.

Case study

The proposed algorithms as discussed in the previous section can allow the robots to follow predefined formations such as V-shape, circular, or line shape. Due to their
similarity, we just present two cases of V-shape and circular shape. Let \( p_l = (x_l, y_l)^T \) and \( p_t = (x_t, y_t)^T \) be the positions of the leader and the target, respectively. The relative position vector between the leader and the target is \( (p_l - p_t) = (x_l - x_t, y_l - y_t)^T \), and the distance between them is determined as \( d = \sqrt{(x_l - x_t)^2 + (y_l - y_t)^2} \).

**V-shape formation**

Firstly, in order to build the V-shape desired formation, we design the right side of this V-shape based on the desired formation angle \( \phi_d \) and the relative position between the leader and the target. As presented in Figure 5, the coordinates of the base node \( q_\mu \) on the coordinate system \( x'y' \) \((q'_\mu = (x'_\mu, y'_\mu)^T)\) are determined as follows

\[
\begin{pmatrix} x'_\mu \\ y'_\mu \end{pmatrix} = \| q_\mu - p_l \| \begin{pmatrix} \cos \delta_d \\ \sin \delta_d \end{pmatrix}
\]

(37)

where the angle \( \delta_d = \angle(q_\mu - p_l), (p_l - p_t) \) is equal to \( \phi_d / 2 \) and \( \phi_d > 0 \) is the desired formation angle (see Figure 5). The base node \( q_\mu \) is employed to generate virtual nodes on the right side of the V-shape. It lies on the line which deviates with an angle of \( \delta_d \) from the line connecting the leader and the target. The distance between the base node \( q_\mu \) and the leader is equal to the distance of consecutive virtual nodes on the right wing of the V-shape. By rotating and translating equation (37) according to coordinate systems \( x'y' \) and \( xy \), we obtain the position of the desired node \( q_\mu \) on the coordinate system \( xy \) as follows

\[
q_\mu = p_l + Rq'_\mu
\]

(38)

From base node \( q_\mu \) and the position of the leader, we determine a unit vector along the line connecting from \( q_\mu \) to \( p_l \) as \( n_{\mu l} = (p_l - q_\mu) / \| p_l - q_\mu \| \). The rotational matrix \( R \), which depends on the rotational angle \( \theta \), is determined as

\[
R = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}, \text{ if } \theta \text{ rotates clockwise}
\]

\[
\begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix}, \text{ otherwise}
\]

(39)

Now, a virtual node \( j \) \((d_j = \| p_l - q_j \| = jd; q_j = (x_j, y_j)^T; v_j = (v_{xj}, v_{yj})^T; j = 1, 2, ..., N^* ; N^* \in R)\) is determined by the unit vector \( n_{\mu l} \) as

\[
(q_j - p_l) = jdn_{\mu l}
\]

(40)

Here, \( d \) is the distance between any two consecutive nodes. Note that \( \| p_l - q_\mu \| = d \). Substituting \( n_{\mu l} = (p_l - q_\mu) / \| p_l - q_\mu \| \) into equation (40), we obtain

\[
q_j = (1 + j)p_l - jq_\mu
\]

(41)

Equation (41) can be rewritten as

\[
\begin{pmatrix} x_j \\ y_j \end{pmatrix} = \begin{pmatrix} x_l \\ y_l \end{pmatrix} + \begin{pmatrix} jx_\mu \\ jy_\mu \end{pmatrix}
\]

(42)

Equation (42) shows that when \( j \) changes from \( j = 1 \) to \( j = N^* \), we obtain the formation of the \( N^* \) virtual nodes. These nodes lie on a line connecting \( p_l \) and \( q_\mu \) and are equally spaced (the right side of the desired V-shape formation; see Figure 5).

Similarly, the virtual node \( j \) on the left side of the V-shape is designed as

\[
(q_j - q_l) = jdn_{\eta}\eta
\]

(43)

where \( n_{\eta l} = (q_\eta - p_l) / \| q_\eta - p_l \| \) is a unit vector. Hence,

\[
q_j = (1 - j)p_l + jq_\eta
\]

(44)

where \( q_\eta \) is the position of the base node on the line which deviates from the line through the leader and the target with an angle of \( (\pi - \delta_d) \) (see Figure 5). The base node \( q_\eta \) of the left side is similar to the base node \( q_\mu \) of the right side of the V-shape. The distance between the base node \( q_\eta \) and the leader is equal to the distance of consecutive virtual nodes on the left wing of the V-shape. Similar to equation (38), this base node is determined as

\[
q_\eta = p_l + Rq'_\eta
\]

(45)

Using equation (45), we obtain the formation of the virtual node \( j \). They lie on the line through \( p_l \) and \( q_\eta \) and are equally spaced (the left side of the V-shape; see Figure 5). Finally, the law to generate the desired V-shape formation of the virtual nodes \( j \) \((j = 1, 2, ..., N)\) is proposed as
The position of the virtual nodes \( q_j (j = 1, 2, ..., N) \) on the circle, whose central point is at the target’s position \( p_t \) and whose radius is \( d_j^t = \| p_t - p_j \| \), is computed as

\[
q_j = p_t + Rd_j^t, j = 1, 2, ..., N
\]  

(48)

The position of the virtual node \( q_j \) on the coordinate system \( x'y' (q_j' = (x_j', y_j')^T) \) is computed as

\[
\begin{pmatrix}
x_j'
\end{pmatrix} = d_j^t \begin{pmatrix}
\cos(2j\pi/N)
\
\sin(2j\pi/N)
\end{pmatrix}, j = 1, 2, ..., N
\]  

(49)

Let the virtual node owned by the leader be the first position in the circular desired formation. Substituting equation (49) into equation (48), we have the circular formation of the virtual node \( q_j \) as follows

\[
\begin{pmatrix}
x_j
\end{pmatrix} = \begin{pmatrix}
x_t
\end{pmatrix} + Rd_j^t \begin{pmatrix}
\cos(2\xi_j\pi/N)
\
\sin(2\xi_j\pi/N)
\end{pmatrix}, j = 1, 2, ..., N; \xi_j = 1
\]  

(50)

Equation (50) shows that the distributed virtual nodes \( q_j \) \( (j = 1, 2, ..., N) \) on the circular desired formation are equivalent distance, and the distance from them to the target is \( d_j^t = \| p_t - p_j \| \) (see Figure 6(b)). The desired radius is chosen such as the distances among agents guarantee collision avoidance when the circle formation is achieved.

**Simulation results**

In this section, we use the V-shape and circular desired formations, which are built in section *Case study*, to illustrate the proposed control algorithms. We assume that the initial velocities of the robots and the target are zero. The
Achievement of desired formation

For this simulation, the formation angle is selected as $\phi(t) = 2\pi/3$. The proposed algorithms were used to generate the desired formations (V-shape and circular shape) and control the robots to move toward the virtual nodes in the desired formation (algorithm 1).

The results in Figure 7 show that the desired formations were easily created. Robots, which have random initial positions, quickly achieved the desired positions in these desired formations while tracking a moving target without collisions. The position permutations among the members in the formation appeared, but they did not influence the structure of the formation when tracking the target. As shown in Figure 7, at the initial time, one robot was chosen as the leader to drive its formation toward the target in a V-shape formation. At time $t = 70$ s, the V-shape formation was constructed, and it was kept until the square robot detected the obstacle $O_1$. At time $t = 160$ s, while avoiding the obstacle $O_1$, the virtual node, which was owned by the square robot, became a free node. Then, this virtual node attracted the triangular robot to become the active node at time $t = 200$ s. After escaping the obstacle, the square robot quickly approached the remaining free node of the desired formation, as shown in Figure 7. Similarly, the rhombus robot was permuted with other robots in the formation while avoiding the obstacle $O_2$. At time $t = 250$ s, the V-shape formation changed to the circular formation to encircle the target. In this situation, the member robots became the free robots, and then they approached the desired circular formation. Figure 8 shows that this circular formation was kept around the target at the desired radius $r^*$ at time $t = 320$ s. In other words, the leader’s position is stable at the equilibrium point, at which $||p_l - p_r|| = r^*$.

Next we consider the connection of a swarm when the leader was trapped in the complex obstacle (e.g. U-shape obstacle; see Figure 9). In this situation, the actual leader had to transfer its leadership to other members in the swarm, and managed to escape this obstacle. Figure 10 shows that, at time $t = 0$ s, the square robot was chosen as the leader, and its leadership was kept until it was trapped in the U-shape obstacle at time $t = 200$ s. While avoiding obstacle, the square leader transferred its leadership to the triangular robot, which was not faced with any obstacles and closest to the target. Then, this square leader became a free robot. It automatically found a way (lilac

---

**Figure 8.** The distance between the leader and the target in case the leader is not hindered while tracking a moving target.
way) to escape this U-shape obstacle in order to continue following its formation.

After receiving the leadership, the triangular robot reorganized a new formation and continued to lead this formation to track the target. The distance between the new leader and the target shrunk until it achieved the active radius of the circular desired formation \( r_t = \frac{k}{\sqrt{\pi C_0}} \). Then, this distance was maintained to encircle the moving target (see Figure 10). Moreover, Figure 9 shows that the position permutation between the square leader and the triangular leader did not influence the structure of the formation.

The robustness of the swarm in noisy environment

In this subsection, we examine the robustness of the formation under the influences of noise and the change of the formation angle. Distances and velocities of agents are affected by noises, whose profiles are the Gaussian function with zero mean and variance of 1 (see Figure 11). The formation angle \( \phi(t) \) is used for simulations as \( \phi(t) = 2\pi/3 + 1.6\sin(0.2t) \) (see Figure 12).

Figure 14 shows that robot \( i \) was always close to active node \( j \) in the desired formation, and its formation was
maintained following the desired formations (V-shape and circular formation) under the influence of the noisy environment and the changes of the formation angle $\phi(t)/2$. The position error between each robot $i$ and active node $j$, at which this robot $i$ was occupying, is small (see Figures 12 and 13). Figure 14 also reveals that from the random initial positions, the free robots quickly found their desired position in the desired V-shape formation. Then, they tracked a moving target in a stable V-shape formation. At time $t = 70$ s, under the influence of the sudden change of the formation angle from $\phi = 2\pi/3$ to $\phi = (\pi - 0.6)$, the formation was broken, but it was quickly redesigned to continue to track the moving target. In contrast, when the formation angle $\phi(t)$ changed slowly, the formation of robots was always maintained following the desired V-shape formation with the small position errors (see Figures 13 and 14). Moreover, the simulation results show that the noise had influences on the position errors of the robot formation, but they only caused small formation changes, as shown in Figure 13.

Figure 14. The influences of noises and the different formation angles on the swarm’s trajectory while tracking a moving target.

Conclusion

In this article, a new method for decentralized formation control of autonomous robots has been presented, in which the swarm tracks a moving target in a dynamic and noisy environment. The robot system can form predefined formations such as V-shape or circular shape while avoiding collisions among agents of the swarm. The new mechanism which combines the rotational and the repulsive forces can drive robots to quickly escape complex obstacles such as those with concave shapes. The theoretical analysis of the proposed algorithm is given. In our future research, the proposed approach would serve as a framework for addressing the formation control of multiagent systems in two-dimensional space such as unmanned aerial vehicles and underwater robots.
